The Appeal of Information Transactions

Antonio Cabrales, Olivier Gossner and Roberto Serrano*

December 2013

Abstract: An information transaction entails the purchase of information. Formally, it consists of an information structure together with a price. We develop an index of the appeal of information transactions, which is derived as a dual to the agent’s preferences for information. The index of information transactions has a simple analytic characterization in terms of a formula that depends on the relative entropy from priors to posteriors. That formula is, strikingly, the same as the one for free energy in theoretical physics. The index also connects naturally with a recent index of riskiness.

JEL classification numbers: C00, C43, D00, D80, D81, G00, G11.

Keywords: informativeness, information transactions, free energy, Kullback-Leibler divergence, relative entropy, decision under uncertainty, investment, Blackwell ordering.

Serrano: Department of Economics, Brown University, roberto_serrano@brown.edu. We are grateful to Mihailo Backović, Héctor Calvo, Eddie Dekel, and Phil Reny for helpful comments and encouragement. We thank Judith Levi for her excellent editing job. Financial support for Cabrales from the Ministry of the Economy and Competitiveness through grant ECO2009-10531 is gratefully acknowledged.
1 Introduction

Economic agents are constantly receiving new information, yet not all new information is equally valuable. Hence, we often want to measure the informational content of different signals, and both economists and information theorists have devoted much effort to this measurement problem. In addition, new information is often not obtained for free: one has to pay for it. What sets this paper aside from previous contributions is the consideration of this information/price tradeoff, in what we call information transactions. An information transaction is defined as a pair consisting of an information structure and a price. If we were sick and wanted a diagnosis, we could hire a famous specialist who also charges high fees for it, or we could settle for a cheaper expert who probably would provide a less accurate diagnosis. We aim to find a way to assess “objectively” the relative worth of each of those information transactions.

These questions are heavily inspired by Blackwell (1953), who introduces a ranking of information structures in terms of their informativeness, and shows that an information structure $\alpha$ is more informative than another information structure $\beta$ if every decision maker prefers $\alpha$ to $\beta$ in every decision problem. Blackwell’s approach has a limited scope for applications, because it does not provide a complete ordering. Researchers have made progress by focusing on decision makers who have preferences in a particular class. This paper takes a different route that allows us to rank information transactions completely: we develop an index of the appeal of information transactions that is dual to the agent’s preferences for information, as we now briefly describe.

Agents with a stronger preference for information should, ceteris paribus, like to acquire information more often. However, different agents have different preferences for information, and not all agree on their rankings of information transactions, an implication of Blackwell’s result. In another way to put it, in a consistent theory of what it means for an agent $u_1$ to like information more than $u_2$, and for an information transaction $a_1$ to be

---

1Veldkamp (2011) describes many of the ways in which economists have measured informativeness and their applications.

more appealing than \( a_2 \), in this setup, whenever \( u_2 \) accepts \( a_2 \), \( u_1 \) should also accept \( a_1 \). The contribution of this paper is to show how this approach, surprisingly, leads to an essentially unique and complete ranking over all information transactions.

Indeed, we examine three alternative approaches to ordering preferences for information. To be more precise, “\( u_1 \) likes information better than \( u_2 \)” can mean: (1) “If \( u_2 \) accepts a transaction at some wealth level, then \( u_1 \) accepts it at any wealth level” (uniform comparison); or (2) “If \( u_2 \) accepts a transaction at some wealth level, then \( u_1 \) accepts it at some wealth level”, (minimal comparison), or (3) “If \( u_2 \) accepts at some wealth level \( w \), then \( u_1 \) also accepts at \( w \) for every \( w \)” (wealth wise comparison).

For each of these orderings, we introduce a suitable corresponding ordering of information transactions according to the duality principle that “if \( u_1 \) likes information better than \( u_2 \) and if \( a_1 \) is more appealing than \( a_2 \), \( u_1 \) should accept \( a_1 \) if \( u_2 \) accepts \( a_2 \)”. Strikingly, all three orderings of information transactions coincide, all three yield the same complete ordering, and we characterize this ordering with an analytical formula.

In constructing the index, we discover novel results - which are of interest in their own right and can be very useful in applications - regarding the connection between a decision maker’s risk attitudes and the value of information for him. More precisely, we show that (1) an agent \( u_1 \) uniformly likes information more than agent \( u_2 \) if and only if the maximum coefficient of risk aversion of \( u_1 \) is lower than the minimum coefficient of risk aversion of \( u_2 \), (2) for agents with decreasing absolute risk aversion (DARA), \( u_1 \) minimally likes information better than \( u_2 \) if and only if the infimum level of risk aversion is lower for \( u_1 \) than it is for \( u_2 \), and (3) \( u_1 \) wealth wise likes information better than \( u_2 \) if and only if at every wealth level, the coefficient of risk aversion is lower for \( u_1 \) than it is for \( u_2 \). In particular, the “minimally likes information” ordering is complete among DARA agents, while the other two are incomplete. We then use these results to show that the appeal of an information transaction \( a \) is actually the risk aversion coefficient of the CARA (constant absolute risk aversion) agent who is indifferent between accepting and rejecting \( a \).

The duality principle described above can only provide an ordinal characterization of the concept of appeal of transactions. It turns out that the appeal index also satisfies the additional property of \textit{price homogeneity of degree -1}. Price homogeneity conveys a sort of separability between information and price in assessing the appeal of an information transaction: when
two transactions are ranked in a certain order, multiplying the price of a
transaction by a constant divides its appeal by this constant. This implies in
particular that multiplying the price of two transactions by the same constant
does not alter their ranking. The homogeneity degree is negative because we
seek indices that are decreasing with the price $\mu$. Next, we offer an axiomatic
characterization of the appeal of information transactions. *Duality* and *homogeneity* define the index uniquely, up to a multiplicative normalization
constant.

The results described in the previous paragraphs lead to a simple charac-
terization of the index, given that CARA agents have investment strategies
which are easy to express analytically. In words, the index depends nega-
tively on the price of the transaction and positively on the relative entropy
from the prior to the posteriors generated by the signals of the information
structure. The presence of relative entropy in the index is interesting because
this relative entropy, which is also called Kullback-Leibler divergence (after
Kullback and Leibler, 1951), is often used in other sciences as a measure
of information gain. We remark, however, a surprising finding: our appeal
ordering is not represented by relative entropy; the way relative entropy en-
ters our index *must be exactly the same* as in the formula for free energy in
theoretical physics, or the formula for stochastic complexity in machine learn-
ing (Subsection 7.4 discusses this issue). We find these connections across
disciplines both amazing and reassuring.

The approach in this paper is very much inspired by that of Aumann
and Serrano (2008) for ordering riskiness. The parallels between the indices
for informativeness and riskiness are actually rather striking; for example,
both indices attribute central importance to the CARA agents, and their
respective axiomatic characterizations use identical axioms. This suggests
that duality is a powerful principle for ordering multidimensional objects,
far beyond the riskiness of one-dimensional random variables.

In Cabrales, Gossner, and Serrano (2013), we have provided another infor-
mation index. In that paper, the informativeness of an information structure
is characterized by the reduction of entropy from the prior. With a uniform
prior, and for small amounts of information, that index is close to the index
proposed here when the transaction price is kept constant, but they differ
significantly when the amount of information in the signals is larger. The
methodology we use here differs significantly and complements the approach
used in Cabrales, Gossner, and Serrano (2013). In that paper, we are asking
whether the maximal price any agent in the economy is willing to pay for
one piece of information is larger than the maximal for the other piece of
information, while all agents are held at the same wealth level. In this pa-
per, we allow wealth levels to differ across agents, and we compare the sets
of agents who are willing to accept a transaction with the sets of agents who
are willing to accept another one. Hart (2011) provides this comparison of
orderings for indices of riskiness.

Here is how the paper proceeds. Section 2 describes the model. Section 3
defines an ordering of information transactions based on agents’ preferences
for information. Section 4 presents our main result, connects the notions of
risk aversion and value of information, and relates the notion of appeal to
CARA agents. Section 6 provides other characterizations of the index: both
a cardinal axiomatization and a perspective based on the total rejection of
information transactions. Section 7 presents a number of properties of the
index and provides some examples. Relevant literature is discussed in Section
8, and Section 9 concludes. The proofs are in the appendix.

2 The Model

2.1 The Agent

We consider an investor with initial wealth $w$ and a monetary utility function
$u$ defined on $\mathbb{R}$. We assume that $u$ is nondecreasing, concave and twice
differentiable. We let $\mathcal{U}$ be the set of such monetary utility functions. We
identify agents by their monetary utility functions, thus speaking of agent $u$
to refer to an agent with utility function $u$.

2.2 Investments

There is a finite set $K$ of states of nature, about which the agent is uncertain.
The agent’s prior on $K$ is $p \in \Delta(K)$, assumed to have full support. The set
of investment opportunities consists of all no-arbitrage assets given $p$, that is,
assets with a nonpositive expected return: $B^* = \{x \in \mathbb{R}^K : \sum_k p_k x_k \leq 0\}$.\(^3\)

\(^3\)The vector $p = (p_k)_k$ in the definition of no-arbitrage assets corresponds to the price
vector of Arrow-Debreu securities, where $p_k$ can be interpreted as the price of an asset
that pays 1 in state $k$ and 0 in all other states. The fact that this vector coincides with
the agent’s prior $p$ means that no-arbitrage assets cannot yield a positive expected return.
We disentangle the two roles of $p$, price and priors, in Section 7.2.
When the agent’s initial wealth is $w$, $b$ is chosen and state $k$ is realized, the agent’s final wealth is $w + b_k$.

2.3 Information Transactions

Before choosing an investment, the agent has the opportunity to engage in a (costly) information transaction $a = (\mu, \alpha)$. Here, $\mu > 0$ represents the cost of the information transaction, and $\alpha$ is the information structure representing the information obtained from $a$. That is, $\alpha$ is given by a finite set of signals $S_\alpha$, together with probabilities $\alpha_k \in \Delta(S_\alpha)$ for every $k$. When the state of nature is $k$, then $\alpha_k(s)$ is the probability that the signal observed by the agent is $s$. It is standard practice to represent any such information structure by a stochastic matrix, with as many rows as states and as many columns as signals; in the matrix, row $k$ is the probability distribution $(\alpha_k(s))_{s \in S_\alpha}$. Signal $s$ has a total probability $p_\alpha(s) = \sum_k p_k \alpha_k(s)$, and we assume, without loss of generality, that $p_\alpha(s) > 0$ for every $s$. For each signal $s \in S_\alpha$, we let $q^s_k \in \Delta(K)$ be the probability of state $k$ conditional on $s$ computed using Bayes’s rule.

We say that $a$ is excluding if for every signal $s$, there exists $k$ such that $q^s_k = 0$. It is nonexcluding otherwise. Excluding information transactions are such that, for every received signal, there exists a state of nature that the agent can exclude.

2.4 Optimal Investment after Receiving Information

Given a belief $q$, an agent with wealth $w$ and utility $u$ chooses $b \in B^*$ in order to maximize his expected utility over all states $k \in K$. The maximum expected utility is then $V(u, w, q)$, given by:

$$V(u, w, q) = \sup_{b \in B^*} \sum_k q_k u(w + b_k).$$

2.5 Acceptance of Information Transactions

The agent with utility function $u$ and wealth $w$ accepts an information transaction $a = (\mu, \alpha)$ if and only if paying $\mu$ upfront to receive information according to $\alpha$ generates an expected utility greater than or equal to staying
with wealth $w$. This is the case if and only if:

$$\sum_s p_\alpha(s) V(u, w - \mu, q^*_k) \geq u(w).$$

## 3 More Appealing Information Transactions

This section proposes a way to define the “objective” appeal of information transactions. The approach is based on ordering preferences for information.

### 3.1 Ordering Preferences for Information

Our first task is to define what it means for an agent to like information better than another one. The theory of ordering preferences for information is, as far as we know, new, and of interest on its own. In general terms, an agent $u_1$ likes information better than another agent $u_2$ when $u_1$ accepts information more often than $u_2$. In order to make the definition precise, we need to be careful both about the wealth levels at which we compare $u_1$ and $u_2$ acceptance and rejection of information transactions.

Our definition requires agent $u_1$ to accept the information transaction at all wealth levels whenever $u_2$ accepts it at some wealth level. Alternative definitions are studied in Section 5.

**Definition 1** Let $u_1, u_2 \in U$ be two agents with utilities defined over $\mathbb{R}$. We say that $u_1$ uniformly likes information better than $u_2$ if, for every pair of wealth levels $w_1, w_2$, and information transaction $a$, whenever agent $u_2$ accepts $a$ at wealth $w_2$, then agent $u_1$ does so at wealth $w_1$.

### 3.2 Ordering Information Transactions

We move now to define the comparative appeal of two information transactions based on the rankings over preferences for information.

**Definition 2** Let $a_1, a_2$ be two information transactions. We say that $a_1$ is uniformly more appealing than $a_2$ if, given two agents $u_1, u_2 \in U$ such that $u_1$ uniformly likes information better than $u_2$ and given two wealth levels $w_1, w_2$, whenever agent $u_2$ accepts $a_2$ at wealth level $w_2$, then agent $u_1$ accepts $a_1$ at wealth level $w_1$. 

7
4 The Main Result

For two probability distributions $p$ and $q$, the relative entropy from $p$ to $q$, also called their Kulback-Leibler divergence, has been proposed as a nonsymmetric measure of their discrepancy. It is defined as follows:

\[ d(p\|q) = \sum_k p_k \ln \frac{p_k}{q_k}. \]

It is always nonnegative, and equals zero if and only if $p = q$. It is finite provided the support of $q$ contains that of $p$, and we let it take the value $+\infty$ otherwise. Thus, $p$ and $q$ are “maximally different” when $q$ rules out one possibility that $p$ does not.\(^4\)

Based on the relative entropy, we define the appeal of an information transaction $a$ as this quantity:

\[ A(a) = -\frac{1}{\mu} \ln \left( \sum_s p_\alpha(s) \exp(-d(p\|q_\alpha^s)) \right). \] (1)

In the above formula, and throughout the paper, we use the convention $\exp(-d(p\|q_\alpha^s)) = 0$ by continuity if $d(p\|q_\alpha^s) = +\infty$. The appeal $A(a)$ of $a$ is thus well-defined and finite if and only if there exists $s$ such that $-d(p\|q_\alpha^s)$ is finite, which is the case if $a$ is nonexcluding. We let $A(a) = +\infty$ if $a$ is excluding.

The appeal of an information transaction decreases with its price and increases with the relative entropy of the prior to the posteriors. Specifically, the appeal of an information transaction is measured by the inverse of its price multiplied by the natural logarithm of the expected exponentials of the negative of relative entropy from the prior to each of the generated posteriors.\(^5\)

Our central result below asserts that $A$ properly measures the appeal of information transactions:

\(^4\)If $p$ were the true distribution and $q$ an approximate hypothesis, information theory views the relative entropy from $p$ to $q$ as giving the expected number of extra bits required to code the information if one were to use $q$ instead of $p$.

\(^5\)If we ignore the price $\mu$, this same formula is referred to as “free energy” in theoretical physics (see, e.g., Landau and Lifshitz, 1980), where relative entropy plays the role of the Hamiltonian of the system. Similar formulas appear under the term “stochastic complexity” in machine learning (Hinton and Zemel, 1994)
Theorem 1 Let $a_1$ and $a_2$ be two information transactions. Then, $a_1$ is more appealing than $a_2$ if and only if $A(a_1) \geq A(a_2)$.

To illustrate the appeal ranking measured by Theorem 1, we make the following observations. The maximal elements for the appeal ranking of information transactions are all excluding transactions, since for them the appeal is infinite. The ordering does not discriminate between excluding transactions: all of them allow an investor to become infinitely rich with probability one by betting against a state just found out to be impossible, regardless of any finite transaction price. Of course, typically it will be difficult to completely rule out a state, and thus we view excluding transactions as limiting extreme cases. On the other hand, the other extreme examples are the minimal elements of the ordering, which are the information transactions that involve completely uninformative information structures (i.e., $\alpha_k = \alpha_{k'}$ for every two states $k$ and $k'$). In this case, the appeal is zero. These information structures are of no value to an investor, who, viewed as an information shopper, sees they are worthless, captured by their null appeal independently of the price. Away from these two extreme cases, the appeal formula provides a finer quantification of the tradeoff between quality of information and its price. Also, if $a_1 = (\mu_1, \alpha_1)$ and $a_2 = (\mu_2, \alpha_2)$ are ranked in a certain way in terms of their appeal, then for any $\lambda > 0$, $b_1 = (\lambda \mu_1, \alpha_1)$ and $b_2 = (\lambda \mu_2, \alpha_2)$ are ranked in the same way, which represents a price homogeneity or separability property.

The next subsections pave the way to prove Theorem 1, and the results contained in them have interest in their own right. We begin with connecting preference for information with risk aversion.

4.1 Risk Aversion and Preference for Information

Given $u \in U$ and $w \in \mathbb{R}$, let $\rho_u(w) = -\frac{u''(w)}{w'(w)}$ be the Arrow-Pratt coefficient of absolute risk aversion of agent $u$ at wealth $w$. We also let $\overline{R}(u) = \sup_w \rho_u(w)$, and $\underline{R}(u) = \inf_w \rho_u(w)$.

Theorem 2 Given $u_1, u_2 \in U$, $u_1$ uniformly likes information better than $u_2$ if and only if $\overline{R}(u_1) \leq \underline{R}(u_2)$.

Theorem 2 establishes the connection between preference for information and risk aversion. Lemma 2 in Cabrales, Gossner, and Serrano (2013) shows
that an agent with ln utility accepts an information transaction whenever a more risk-averse agent does. Theorem 2 both extends this result to general pairs of utility functions, and shows that a converse result holds, namely, that an agent who likes information better than another is necessarily less risk-averse. The proof of this converse part is somewhat more involved as for the direct part, as one needs to derive a conclusion about the risk aversion levels of the agents at all wealth levels.

4.2 CARA Agents

Recall the class of CARA (constant absolute risk aversion) utility functions. Given \( r > 0 \), let \( u^r_C \) be the CARA utility function with parameter \( r \) given by
\[
  u^r_C(w) = -\exp(-rw)
\]
for every \( w \).

**Theorem 3** Let \( a \) be an information transaction and \( w \) be any wealth level.

1. If \( r > A(a) \), then an agent with utility \( u^r_C \) rejects \( a \) at wealth \( w \).
2. If \( r \leq A(a) \), then an agent with utility \( u^r_C \) accepts \( a \) at wealth \( w \).

Theorem 3 shows that \( A(a) \) can be equivalently defined as the level of risk aversion such that every CARA agent who is more risk-averse rejects \( a \), whereas every CARA agent who is less or equally risk-averse accepts it. Theorem 3 is also a key step in the proof of Theorem 1.

It is interesting to see how Theorem 3 particularizes for excluding information transactions and completely noninformative ones. If \( a \) is excluding, then \( A(a) = +\infty \), and the theorem shows that all CARA agents accept \( a \). If \( a \) is completely noninformative, then \( A(a) = 0 \) and the theorem shows that it is rejected by all CARA agents.

5 Alternative comparisons of preferences for information

Definition 1 provides a ranking over preferences for information. This ranking is highly incomplete, as an implication of Theorem 2 is that many pairs of agents are not comparable by the “uniformly likes information better” ranking. Since rankings of preferences for information are of interest in their own right, we examine two alternative definitions thereof, one of which being
a complete ordering over agents with decreasing risk aversion. It will be apparent that the ranking introduced in Definition 1 and the two alternative rankings introduced in this section differ significantly.

Following a parallel approach to Definition 2, we define orderings of information transactions according to a monotonicity property with respect to each of the alternatives concerning preferences for information. Somewhat surprisingly, all the obtained rankings of information transactions coincide and are characterized by the appeal quantity \( A(\cdot) \).

The first alternative definition of a ranking for preferences for information requires agent \( u_1 \) to accept the information transaction at some wealth levels whenever \( u_2 \) accepts it at some wealth level. This is thus weaker than the definition of uniformly liking information better that requires \( u_1 \) to accept the information at all wealth levels whenever \( u_2 \) accepts it at some wealth level. We restrict attention to agents who are in the class \( U_{DA} \) of utility functions \( u \) that are defined over \( \mathbb{R} \) or \( \mathbb{R}_+ \), twice differentiable, and such that \( \rho_u \) is decreasing in wealth (DARA).

**Definition 3** Let \( u_1, u_2 \in U_{DA} \). We say that \( u_1 \) minimally likes information better than \( u_2 \) if, for every information transaction \( a \), and for every \( w_2 \), there exists \( w_1 \) such that, if \( u_2 \) accepts \( a \) at \( w_2 \), then \( u_1 \) accepts it at \( w_1 \).

This definition is an extremely weak requirement and it is capable of ordering a large set of agents, as will be shown shortly.

Our second alternative definition requires the wealth levels at which \( u_1 \) and \( u_2 \) are compared to be identical. It allows utilities to be defined over any bounded or unbounded open interval. We let \( U_{DA}^I \) of utility functions \( u \) that are defined over an open interval of \( \mathbb{R} \), twice differentiable, and such that \( \rho_u \) is decreasing. The following definition is general in that it allows the wealth intervals on which the two agents we compare are defined to differ.

**Definition 4** Let \( u_1, u_2 \in U_{DA}^I \), with \( u_1 \) defined over \( I_1 \) and \( u_2 \) over \( I_2 \). We say that \( u_1 \) wealth wise likes information better than \( u_2 \) if \( I_1 \supseteq I_2 \) and, for every information transaction \( a \) and wealth level \( w \), if \( u_2 \) accepts \( a \) at \( w \), then so does \( u_1 \).

For agent \( u_1 \) to wealth wise like information better than \( u_2 \), it is required that \( u_1 \) accepts information transactions more often than \( u_2 \), when the comparison holds at the same wealth level. Since \( u_1 \) cannot accept information
transactions for wealth levels outside of $I_1$, it is necessary that that $I_1$ is a superset of $I_2$.

It is implicit in Definitions 3 and 4 that the agent rejects all information transactions that would make the wealth after purchase $w - \mu$ lie outside of the domain of the utility function $u$. In Section 7.5, we present several examples of pairs of agents who are ranked according to these orderings and show that these orderings are quite distinct from each other.

The following Theorem characterizes the orderings of Definitions 3 and 4 in terms of levels of risk aversion, and it should be compared with Theorem 2.

**Theorem 4**

1. Let $u_1, u_2 \in \mathcal{U}_{DA}$, $u_1$ minimally likes information better than $u_2$ if and only if:
   $$R(u_1) \leq R(u_2).$$

2. Let $u_1, u_2 \in \mathcal{U}^I_{DA}$, with respective domains $I_1$ and $I_2$. Then, $u_1$ wealth wise likes information better than $u_2$ if and only if $I_1 \supseteq I_2$ and:
   $$\forall w \in I_2, \quad \rho_{u_1}(w) \leq \rho_{u_2}(w).$$

In particular, some consequences of Theorem 4 is that the “minimally likes information” ordering is complete over the set of DARA agents, and that the uniform ordering is stronger than the wealth wise ordering which is itself stronger than the minimal ordering. The examples of Section 7.5 show that all three orderings differ.

We now define orderings of information transactions according to monotonicity with regards to the orderings on preferences for information. The two following definitions parallel Definition 2.

First, using the “minimally likes information better” ordering.

**Definition 5** Let $a_1, a_2$ be two information transactions. We say that $a_1$ is minimally more appealing than $a_2$ if, given two agents $u_1, u_2 \in \mathcal{U}_{DA}$ such that $u_1$ minimally likes information better than $u_2$, whenever $u_2$ accepts $a_2$ at some wealth level, $u_1$ also accepts $a_1$ at some wealth level.

And second, relying on the “wealth wise likes information better” ordering.

**Definition 6** Let $a_1, a_2$ be two information transactions. We say that $a_1$ is wealth wise more appealing than $a_2$ if, for every $u_2 \in \mathcal{U}^I_{DA}$, and $u_2 \in \mathcal{U}_{DA}$ such that $u_1$ wealth wise likes information better than $u_2$, if $u_2$ accepts $a_2$ at some wealth level, $u_1$ also accepts $a_1$ at some wealth level.
The definition requires the set of agents \( u_1 \) who accept \( a_1 \) at some wealth level to be neither too large, nor too small. This set is potentially smaller than the set of agents in \( U_{DA}^I \) who like information better than \( u_2 \), but it has to include all elements of \( U_{DA} \) who like information better than \( u_2 \).

We now state characterization of these orderings over information transactions.

**Theorem 5** Let \( a_1, a_2 \) be two information transactions. The three following statements are equivalent:

1. \( a_1 \) is uniformly more appealing than \( a_2 \),
2. \( a_1 \) is minimally more appealing than \( a_2 \),
3. \( a_1 \) is wealth wise more appealing than \( a_2 \).

And in particular, they are all equivalent to:

\[
\mathcal{A}(a_1) \geq \mathcal{A}(a_2).
\]

The theorem shows that, although the three orderings over preferences for information are quite distinct, they lead to the same complete ordering of information transactions, and that ordering is characterized by the appeal \( \mathcal{A}(\cdot) \).

### 6 Other Characterizations of the Appeal

#### 6.1 Axiomatic Characterization

Theorem 1 uses the appeal measured by \( \mathcal{A} \) to characterize the ranking of information transactions based on agents’ preferences for information. The statement of Theorem 1 would remain unchanged if we replaced \( \mathcal{A} \) by any increasing transformation \( f(\mathcal{A}) \). In this sense, the cardinal measure of appeal is not uniquely characterized by Theorem 1. In this subsection we show that \( \mathcal{A} \) is uniquely characterized up to a positive multiplicative constant by two axioms: *duality* and *price homogeneity of degree -1*.

We turn now to the formal definition of the two axioms on the appeal of transactions. Let \( \mathcal{B} \) be a map from information transactions to the nonnegative numbers.
Duality: $\mathcal{B}$ satisfies duality if, given two information transactions $a_1$ and $a_2$, 
$\mathcal{B}(a_1) \geq \mathcal{B}(a_2)$ if and only if $a_1$ is more appealing than $a_2$.

Price homogeneity: $\mathcal{B}$ is price-homogeneous of degree -1 if, for every $a = (\mu, \alpha)$ and $\lambda > 0$,

$$\mathcal{B}(\lambda \mu, \alpha) = \frac{1}{\lambda} \mathcal{B}(\mu, \alpha).$$

We seek an index that ranks the appeal of information transactions. In this context, conceiving of the appeal of information transactions as a “dual” to the preferences for information embodied in Definition 1 seems rather sensible. That is, whenever an agent who likes information less accepts a less appealing information transaction, an agent who likes information more should accept a more appealing information transaction.\(^6\)

Price homogeneity separates information from price in the basic tradeoff we are trying to capture. Once homogeneity is imposed, one can begin by measuring the appeal of all transactions priced at $\$1$.\(^7\) Then, homogeneity extends the appeal measure to all transactions. Furthermore, if the appeal index should take positive values, it ought to be decreasing with $\mu$. This is the reason why the price homogeneity has degree -1 and not 1. Alternatively, we could construct an index having negative values, decreasing with $\mu$, and price-homogeneous of degree 1; this index would be given by $-\frac{1}{\mathcal{B}}$ instead of $\mathcal{B}$.

**Theorem 6** The index $\mathcal{A}$ is the unique index, up to a positive multiplicative constant, that satisfies the axioms of duality and price homogeneity of degree -1.

It is easy to see that the axioms are logically independent in our characterization. If one drops price homogeneity, any nonlinear monotone transformation of the index $\mathcal{A}$ also satisfies duality. If one drops duality, the index $\frac{1}{\mu} I_e(\alpha)$ satisfies homogeneity, where $I_e$ is the entropy informativeness index proposed in Cabrales, Gossner, and Serrano (2013). Example 2 in Subsection 7.6 argues that the two indices are ordinally different.

\(^6\)In effect, this was the same reason used in Aumann and Serrano (2008) to justify their duality axiom. (In that case, the “duality” was sought between riskiness and risk aversion.)

\(^7\)It turns out that for this class, the connection of our appeal index and free energy is exact.
6.2 An Approach Based on Total Rejections

Following Hart (2011)’s approach (see also Cabrales, Gossner, and Serrano, 2013), we now introduce the definition of uniform wealth-dominance:

**Definition 7** Let \( a_1 \) and \( a_2 \) be two information transactions. We say that \( a_1 \) uniformly wealth-dominates \( a_2 \) if any \( u \in U_{DA} \) that rejects \( a_1 \) at all wealth levels also rejects \( a_2 \) at all wealth levels.

This definition proposes a uniform or total rejection of transactions within the DARA class of preferences. That is, \( a_1 \) uniformly wealth-dominates \( a_2 \) because the latter is rejected more often: whenever \( a_1 \) is rejected at all wealth levels, so is \( a_2 \), but not vice versa. The definition leads to the following result:

**Theorem 7** Let \( a_1 \) and \( a_2 \) be two information transactions. Then, \( a_1 \) uniformly wealth-dominates \( a_2 \) if and only if \( A(a_1) \geq A(a_2) \).

We observe that the same theorem holds if we restrict the class of functions by imposing IRRA and ruin aversion on top of DARA.\(^8\)

7 Some Properties and Examples

7.1 Some Properties of the Appeal Index

Here we discuss several properties of the appeal index.

7.1.1 Continuity

The appeal index \( A \) is jointly continuous in \( \mu \), in \( p_\alpha \), and in \( (q_\alpha^s)_s \) on the domain of nonexcluding information transactions. Continuity is a natural and attractive property: small changes in either the price or the conditional probabilities of signals should translate into small changes in the appeal of the transaction. Recall, however, that \( A(a) = +\infty \) when \( a \) is excluding.

\(^8\)IRRA and ruin aversion are the restrictions on preferences used in Cabrales, Gossner, and Serrano (2013).
7.1.2 Blackwell monotonicity

The appeal index is Blackwell-monotonic, as expressed in the following proposition:

**Proposition 1** If an information structure $\alpha_1$ is more informative than another information structure $\alpha_2$ in the sense of Blackwell, then for any price $\mu > 0$, the information transaction $(\mu, \alpha_1)$ is more appealing than the information transaction $(\mu, \alpha_2)$. Thus we have:

$$A(\mu, \alpha_1) \geq A(\mu, \alpha_2).$$

The results show that the complete ordering defined by the appeal is an extension of Blackwell’s ordering over information structures evaluated at the same price. Since the appeal is a new ordering, the proposition is also a new result. Our simple proof of the proposition does not rely on the analytical form of the appeal function, but rather on its axiomatic characterization.

7.1.3 Mixtures

A third property concerns what happens when an information structure is constructed by randomizing over two other ones. Given information structures $\alpha_1$, $\alpha_2$ and $1 > \lambda > 0$, we let $\lambda \alpha_1 \oplus (1 - \lambda)\alpha_2$ be the information structure in which (i) a coin toss determines whether the agent’s signal is chosen from $\alpha_1$ (with probability $\lambda$) or $\alpha_2$ (with probability $1 - \lambda$), and (ii) the agent is informed of both the outcome of the coin toss and the signal drawn from the chosen information structure. Formally, the set of signals in $\lambda \alpha_1 \oplus (1 - \lambda)\alpha_2$ is $S_{\alpha_1} \cup S_{\alpha_2}$ (where we assume that $S_{\alpha_1}$ and $S_{\alpha_2}$ are disjoint), and the probability in state $k$ that the agent receives signal $s \in S_{\alpha_1}$ is $\lambda \alpha_{1,k}(s)$, whereas the probability of a signal $s \in S_{\alpha_2}$ is $(1 - \lambda)\alpha_{2,k}(s)$.

**Proposition 2** Consider $\mu > 0$ and $\alpha_1$, $\alpha_2$ such that $A(\mu, \alpha_1) \geq A(\mu, \alpha_2)$. For every $1 > \lambda > 0$, we have:

$$A(\mu, \alpha_1) \geq A(\mu, \lambda \alpha_1 \oplus (1 - \lambda)\alpha_2) \geq A(\mu, \alpha_2).$$

7.2 The Role of Prices and Priors

In the model of Section 2, $p$ plays a dual role. Indeed, $p$ is the agent’s prior before he receives any information, and it is also a vector of prices for Arrow-Debreu securities that defines the set of no-arbitrage assets $B^\star$. In order to
both allow for the agent’s prior to be different from the price system, and disentangle the two roles of $p$, we consider here agents whose prior belief $q \in \Delta(K)$ may differ from the vector $p$ defining the set $B^*$.

In this more general model, an agent accepts an information transaction $a = (\mu, \alpha)$ at prior $q$ if and only if:

$$\sum_s p_\alpha(s)V(u, w - \mu, q^\alpha_s) \geq V(u, w, q),$$

where $q^\alpha_s$ is the agent’s posterior belief after receiving a signal $s$ given the prior $q$. Note that if $q = p$, then $V(u, w, q)$ equals $u(w)$ so that the definition particularizes to the original one in this case.\footnote{It is convenient to write the RHS of this expression this way, given our analysis of sequential transactions in the next subsection.}

Our Definition 2 extends as follows: We say that $a_1$ is more appealing than $a_2$ at prior $q$ if, given two agents $u_1, u_2$ such that $u_1$ uniformly likes information better than $u_2$ and two wealth levels $w_1, w_2$, whenever agent $u_2$ accepts $a_2$ at wealth level $w_2$ and prior $q$, then agent $u_1$ accepts $a_1$ at wealth level $w_1$ and prior $q$.

Then, we define the appeal of an information transaction $a = (\mu, \alpha)$ at prior $q$ as:

$$A(a, q) = \frac{1}{\mu} \ln \left( \sum_s p_\alpha(s) \exp(-d(p\|q^\alpha_s)) \right) - \frac{d(p\|q)}{\mu} = A(a) - \frac{d(p\|q)}{\mu}.$$

As a word of caution, we note that in the formula above, as $(q^\alpha_s)_s$ depends on $q$, so does $A(a)$. Theorems 1 and 3 can be extended as Theorems 8 and 9 respectively:

**Theorem 8** Let $a_1$ and $a_2$ be two information transactions. Then, $a_1$ is more appealing than $a_2$ at prior $q$ if and only if $A(a_1, q) \geq A(a_2, q)$.

**Theorem 9** Let $a$ be an information transaction and $w$ be any wealth level.

1. If $r > A(a, q)$, then an agent with utility $u_C^r$ rejects $a$ at wealth $w$ and prior $q$.

2. If $r \leq A(a, q)$, then an agent with utility $u_C^r$ accepts $a$ at wealth $w$ and prior $q$. 
7.3 Sequential Transactions

The final property we mention concerns the appeal of an information transaction in which the buyer receives signals sequentially from different information structures. Given an information structure $\alpha$ with a set of signals $S_\alpha$ and a family $\beta = (\beta_s)_{s \in S_\alpha}$ of information structures, where all the members of $\beta$ share the same set of signals $S_\beta$, we let $(\alpha, \beta)$ be the information structure in which the agent first receives a signal $s$ from $\alpha$, then an independently drawn (conditional on $k$) signal $s'$ from $\beta_s$. Formally, the set of signals in $(\alpha, \beta)$ is $S_\alpha \times S_\beta$, and in state $k$, the probability of receiving the pair of signals $(s, s')$ is $\alpha_k(s)\beta_{s,k}(s')$. Given an information transaction $a = (\mu, \alpha)$ and a family of information transactions $b = (b_s) = (\nu, \beta_s)_s$, where all the members of $b$ have the same price $\nu$, we let $a + b$ denote the information transaction $(\mu + \nu, (\alpha, \beta))$.

**Proposition 3** Given information transactions $a$ and $b = (b_s)_s$, the following hold:

1. If for every $s$, $A(b_s, q_s) \geq A(a)$, then $A(a + b) \geq A(a)$.
2. If for every $s$, $A(b_s, q_s) \leq A(a)$, then $A(a + b) \leq A(a)$.
3. In particular, if for every $s$, $A(b_s, q_s) = A(a)$, then $A(a + b) = A(a)$.

The proposition relates the appeal of an information transaction involving $(\alpha, \beta)$ to the appeal of the information transactions involving $\alpha$ and $(\beta_s)_s$. As a result, the appeal of an information transaction involving $\alpha$ has to be measured given the prior $p$, as in formula (1), but the appeal of an information transaction involving $\beta_s$ has to be measured given the belief $q^*_s$ of the agent after receiving the signal $s$. The proposition makes intuitive sense: if the agent faces a sequence of transactions whose individual appeal is increasing, the appeal of the overall transaction is at least that of the appeal of the first-stage transaction, and so on.

7.4 The Role of $\ln$ and $\exp$ in $A$

So far we have argued that two intuitive properties of the index $A$ are that it makes the appeal of a transaction (i) a decreasing function of its price and (ii) an increasing function of the relative entropy from the prior to each
generated posterior. In this light, one could consider using the following alternative index:
\[
\hat{A}(a) = \frac{1}{\mu} \sum_s p_\alpha(s) d(p\|q_\alpha^*).
\]
It is apparent that the index \(\hat{A}\) retains those two properties, and it also satisfies the desired separability in the form of price homogeneity of degree -1. We know from Theorem 6 that it must violate duality, and indeed, the next example illustrates why it does not rank the appeal of transactions well.

**Example 1** Let \(K = \{1, 2, 3\}\) and fix a uniform prior. Consider, for instance, two information structures with each having two signals:
\[
\alpha_1 = \begin{bmatrix} 0 & 1 \\ 1/2 & 1/2 \end{bmatrix}, \quad \alpha_2 = \begin{bmatrix} 1 - \varepsilon & \varepsilon \\ 1/2 & 1/2 \\ \varepsilon & 1 - \varepsilon \end{bmatrix}
\]

Fix an arbitrary \(\mu > 0\), and define the transactions \(a_1 = (\mu, \alpha_1)\) and \(a_2 = (\mu, \alpha_2)\). Note that \(\hat{A}(a_1) = +\infty\) because the relative entropy of the prior to the posterior generated by the first signal is infinite. On the other hand, for any \(\varepsilon > 0\), \(\hat{A}(a_2)\) is finite. We next argue that the appeal of the transactions is not well measured by \(\hat{A}\). Indeed, for a small enough \(\varepsilon > 0\), the transaction \(a_2\) is almost excluding, and hence, in such a case \(r_1 = \hat{A}(a_1) < \hat{A}(a_2) = r_2\). Here, \(r_1\) and \(r_2\) are the risk-aversion coefficients of the two CARA individuals who define the two corresponding levels of appeal. Let \(r = (r_1 + r_2)/2\). Clearly, the CARA agent \(r\) uniformly likes information more than the CARA \(r_2\) agent; the CARA \(r_2\) agent accepts \(a_2\), which according to the index \(\hat{A}\) would be less appealing than \(a_1\); but agent \(r\) rejects \(a_1\).

The example makes clear the role of the exponential and its compensating logarithm as a “blow up/shrink down” of relative entropies. The exponential function, being bounded above, avoids the problem of infinite relative entropies attached to a single signal. Only when all relative entropies are infinite does the logarithm restore the infinite value of appeal. This is essential in order to satisfy the duality between uniform preferences for information and the proposed function ranking the appeal of transactions.

### 7.5 Examples of Comparisons of Pairs of Agents

Although an implication of Theorem 5 is that the three orderings of preferences for information proposed coincide for CARA agents, this subsection
shows that the three orderings are indeed quite distinct. The first one is the uniform ordering, which is stronger than the wealth wise ordering, itself stronger than the minimal ordering, and indeed, as follows from Theorem 4, the latter is a complete ordering of all DARA utility functions.

We provide two examples of pairs of utility functions, either defined over the whole real line, or on bounded intervals, to show that the three orderings differ.

7.5.1 Sumex Utility Functions

This example uses the sumex utility functions, defined over the entire real line. As shown by Bell (1988), these utility functions, which are in the DARA class, have the following “single switch” property: when comparing two risky gambles, either the agent prefers one to the other at all wealth levels, or there exists a unique critical wealth level at which the decision maker switches from preferring one alternative to the other. Letting $x$ denote final wealth, we thus consider:

$$
\begin{align*}
    u_1(x) &= -\lambda_1 \exp(-r_1 x) - \lambda'_{1\gamma_1} \exp(-r'_1 x) \\
    u_2(x) &= -\lambda_2 \exp(-r_2 x) - \lambda'_{2\gamma_2} \exp(-r'_2 x),
\end{align*}
$$

where all the constants are positive. Then, for agent $i = 1, 2$, the Arrow-Pratt coefficient of absolute risk aversion is such that $\lim_{x \to -\infty} \rho_{u_i}(x) = \max\{r_i, r'_i\}$ and $\lim_{x \to +\infty} \rho_{u_i}(x) = \min\{r_i, r'_i\}$.

Therefore, if $\max\{r_1, r'_1\} > \max\{r_2, r'_2\}$ and $\min\{r_1, r'_1\} < \min\{r_2, r'_2\}$, agent $u_1$ minimally likes information more than agent $u_2$, but $u_1$’s higher preference for information over $u_2$’s is not wealth wise or uniform.

7.5.2 Bounded intervals

The following example illustrates how the ordering of individuals’ preference for information is relevant also over bounded intervals.

For $i = 1, 2, 3$, let

$$
    u_i(x) = \frac{x^{1-\gamma_i}}{1-\gamma_i}
$$

and $(\gamma_1, \gamma_2, \gamma_3) = (1, 2, 4)$. The investment opportunities are such that $\forall x \in B^*$, and $\forall k \in K$, $b_k \in [-25, 25]$. Let the individuals’ initial wealth be $w = 50$, which means that the interval of allowable wealth levels after investment is
I = (25, 75). Suppose this is the interval of final wealth levels that these agents consider, which means that for different initial wealth levels in it, they would adjust downwards the absolute size of their investments.

Then, since

\[ \rho_{u_i}(x) = \frac{\gamma_i}{x} \]

\( (R(u_1), \overline{R}(u_1)) = \left( \frac{1}{75}, \frac{1}{25} \right), \quad (R(u_2), \overline{R}(u_2)) = \left( \frac{2}{75}, \frac{2}{25} \right), \) and \( (R(u_3), \overline{R}(u_3)) = \left( \frac{3}{75}, \frac{3}{25} \right) \). Hence, \( u_1 \) wealth wise likes information more than \( u_2 \), who wealth wise likes information more than \( u_3 \). Transitivity of the relation also implies that \( u_1 \) wealth wise likes information more than \( u_3 \). Furthermore, all these statements can be made for the minimal preference comparison. However, note that while \( u_1 \) uniformly likes information more than \( u_3 \), it is not the case that \( u_1 \) uniformly likes information more than \( u_2 \) or that \( u_2 \) uniformly likes information more than \( u_3 \).

### 7.6 Comparison with Entropy Informativeness

We next present an example, similar to one in Cabrales, Gossner, and Serrano (2013), that illustrates how our framework serves to complete Blackwell’s ordering. In addition, it shows how the information index in our 2012 paper can sometimes provide a different ranking from the induced index of information structures in the current study (when the price of the transaction is kept constant), while it also shows how both can sometimes point in the same direction.

**Example 2** Let \( K = \{1, 2, 3\} \) and fix a uniform prior. Consider two information structures that are not ordered in the sense of Blackwell. For instance, let each of the two information structures have two signals:

\[
\alpha_1 = \begin{bmatrix}
1 - \varepsilon_1 & \varepsilon_1 \\
1 - \varepsilon_1 & \varepsilon_1 \\
\varepsilon_1 & 1 - \varepsilon_1
\end{bmatrix}, \quad \alpha_2 = \begin{bmatrix}
1 - \varepsilon_2 & \varepsilon_2 \\
0.1 & 0.9 \\
\varepsilon_2 & 1 - \varepsilon_2
\end{bmatrix}
\]

For \( \varepsilon_1 \) and \( \varepsilon_2 \) small enough, these information structures are not ranked according to Blackwell. To see this, it suffices to consider two decision problems. In Problem 1, the agent must choose one of two actions: action 1 gives a utility of 1 only in the first two states, and 0 otherwise, while action 2 gives a utility of 1 only in the third state, and 0 otherwise. In contrast, Problem 2 has action 1 pay a utility of 1 only in the first state, and 0 otherwise, while
action 2 gives a utility of 1 only in states 2 or 3, and 0 otherwise. When facing Problem 1, the decision maker would value $\alpha_1$ more than $\alpha_2$: following the first signal in $\alpha_1$, he would choose the first action and following the second signal in $\alpha_1$, he would choose the second action, thereby securing a utility of 1. This would be strictly greater than his utility after $\alpha_2$. On the other hand, when facing Problem 2, he would under $\alpha_2$ choose action 1 after the first signal and action 2 after the second, yielding a utility close to $29/30$, which is greater than his optimal utility after $\alpha_1$.

Now let us compute $A(a_i)$ for $a_1 = (\mu, \alpha_1)$ and $A(a_2)$ for $a_2 = (\mu, \alpha_2)$.

$$A(a_i) = -\frac{1}{\mu} \ln \left( \sum_s p_{\alpha_i}(s) \exp(-d(p\|q^*_{\alpha_i})) \right),$$

and

$$\sum_s p_{\alpha_1}(s) \exp(-d(p\|q^*_{\alpha_1})) = \frac{2 - \varepsilon_1}{3} \exp \left( -\frac{1}{3} \left( \ln \left( \frac{1}{\varepsilon_1} \right) + \ln \left( \frac{1}{\varepsilon_1} \right) + \ln \left( \frac{1}{\varepsilon_1} \right) \right) \right)$$

$$+ \frac{1 + \varepsilon_1}{3} \exp \left( -\frac{1}{3} \left( \ln \left( \frac{1}{\varepsilon_1} \right) + \ln \left( \frac{1}{\varepsilon_1} \right) + \ln \left( \frac{1}{\varepsilon_1} \right) \right) \right)$$

$$\approx \frac{2}{3} \exp \left( -\frac{1}{3} \left( \ln \frac{1}{\varepsilon_1} \right) \right) + \frac{1}{3} \exp \left( -\frac{1}{3} \left( \ln \left( \frac{1}{\varepsilon_1} \right) \right) \right)$$

 $$\approx \frac{2}{3} \varepsilon_1^{1/3} + \frac{1}{3} \varepsilon_1^{2/3}.$$

$$\sum_s p_{\alpha_2}(s) \exp(-d(p\|q^*_{\alpha_2})) = \frac{1.1}{3} \exp \left( -\frac{1}{3} \left( \ln \left( \frac{1}{\varepsilon_2} \right) + \ln \left( \frac{1}{\varepsilon_2} \right) + \ln \left( \frac{1}{\varepsilon_2} \right) \right) \right)$$

$$+ \frac{1.9}{3} \exp \left( -\frac{1}{3} \left( \ln \left( \frac{1}{\varepsilon_2} \right) + \ln \left( \frac{1}{\varepsilon_2} \right) + \ln \left( \frac{1}{\varepsilon_2} \right) \right) \right)$$

$$\approx \frac{1.1}{3} \exp \left( -\frac{1}{3} \ln \varepsilon_2 \right) + \frac{1.9}{3} \exp \left( -\frac{1}{3} \ln \varepsilon_2 \right) = \varepsilon_2^{1/3}.$$

If $\varepsilon_1 = \varepsilon_2$ and both are small enough, then $A(a_2) > A(a_1)$. On the other hand, if $\varepsilon_1 = \varepsilon_2^2$ and both are small, then $A(a_1) > A(a_2)$.

Let us now compute the entropy reduction from the uniform prior, which we denote by $I_e(\cdot)$, letting $H(q) = \sum_{k=1}^{3} -q_k \ln (q_k)$.
\[ I_e(\alpha_1) = H(p) - \sum_{s=1}^{2} p^s_{\alpha_1} H(q^s_{\alpha_1}) \]

\[ = 3 \left( -\frac{1}{3} \ln \left( \frac{1}{3} \right) \right) - \frac{2 - \varepsilon_1}{3} \left( -2 \frac{1 - \varepsilon_1}{2 - \varepsilon_1} \ln \left( \frac{1 - \varepsilon_1}{2 - \varepsilon_1} \right) - \frac{\varepsilon_1}{2 - \varepsilon_1} \ln \left( \frac{\varepsilon_1}{2 - \varepsilon_1} \right) \right) \]

\[ - \frac{1 + \varepsilon_1}{3} \left( -2 \frac{\varepsilon_1}{2 - \varepsilon_1} \ln \left( \frac{\varepsilon_1}{2 - \varepsilon_1} \right) - \frac{1 - \varepsilon_1}{2 - \varepsilon_1} \ln \left( \frac{1 - \varepsilon_1}{2 - \varepsilon_1} \right) \right) \]

\[ \simeq \ln 3 - \frac{2}{3} (\ln 2) - \frac{11}{3} \ln 2 = \ln 3 - \frac{5}{6} \ln 2 \simeq \ln 3 - 0.57762265. \]

\[ I_e(\alpha_2) = 3 \left( -\frac{1}{3} \ln \left( \frac{1}{3} \right) \right) - \frac{1.1}{3} \left( -\frac{1 - \varepsilon_2}{1.1} \ln \left( \frac{1 - \varepsilon_2}{1.1} \right) - \frac{0.1}{1.1} \ln \left( \frac{0.1}{1.1} \right) - \frac{\varepsilon_2}{1.1} \ln \left( \frac{\varepsilon_2}{1.1} \right) \right) \]

\[ - \frac{1.9}{3} \left( -\frac{1 - \varepsilon_2}{1.9} \ln \left( \frac{1 - \varepsilon_2}{1.9} \right) - \frac{0.9}{1.9} \ln \left( \frac{0.9}{1.9} \right) - \frac{\varepsilon_2}{1.9} \ln \left( \frac{\varepsilon_2}{1.9} \right) \right) \]

\[ \simeq \ln 3 - \frac{1}{3} (1.1 \ln 1.1 - 0.1 \ln 0.1 + 1.9 \ln 1.9 - 0.9 \ln 0.9) \]

\[ \simeq \ln 3 - 0.549815518. \]

This implies that \( I_e(\alpha_1) > I_e(\alpha_2) \) whenever \( \varepsilon_1, \varepsilon_2 \) are sufficiently close to zero.

The reason for the difference between entropy informativeness and the approach in this paper is the larger sensitivity of the index \( A \) to information concerning low-probablility events. In particular, \( \alpha_1 \) causes a larger reduction in entropy, being associated with an almost fully informative signal \( s_2 \). In contrast, for equal prices, a purchase of \( \alpha_2 \) is more appealing for sequences of small \( \varepsilon_1 \) and \( \varepsilon_2 \) where \( \varepsilon_1 = \varepsilon_2 \). To understand the latter, note that the limits, as \( \varepsilon_1 \) and \( \varepsilon_2 \) vanish, of \( \alpha_1 \) and \( \alpha_2 \) lead to excluding information transactions, with infinite appeal. The large unbounded appeal of those transactions before going to the limits is explained by the large investments made following each signal. However, in \( \alpha_1 \), following signal \( s_2 \), two states are becoming extremely unlikely, leading the agent to an optimal investment with large losses in these two states, whereas in \( \alpha_2 \) large losses in the optimal investment are confined to only one state. Because of this, when \( \varepsilon_1 \) and \( \varepsilon_2 \) go to zero at the same rate, the large negative utility that a CARA agent derives from large negative wealth implies that \( \alpha_2 \) is more appealing than \( \alpha_1 \). Convergence rates matter, though: this conclusion is overturned if \( \varepsilon_1 \) goes to zero much faster than \( \varepsilon_2 \).
To explore somewhat more systematically the difference between the index based on entropy and the one in this paper, we investigate conditions on “small information” that renders them equivalent. Let \( a_i = (\alpha, \mu) \). We then have the following equation:

\[
\mathcal{A}(a_i) = -\frac{1}{\mu} \ln \left( \sum_s p_{\alpha_i}(s) \exp(-d(p||q_{\alpha_i}^*)) \right)
\]

\[
= -\frac{1}{\mu} \ln \left( \sum_s p_{\alpha_i}(s) \exp \left( - \sum_k p_k \ln p_k - \ln q_{\alpha_i}(k) \right) \right)
\]

\[
I_e(\alpha_i) = - \sum_k p_k \ln p_k - \sum_s p_{\alpha_i}(s) \left( \sum_k q_{\alpha_i}^*(k) \ln q_{\alpha_i}^*(k) \right)
\]

\[
= \sum_s p_{\alpha_i}(s) \left( \sum_k p_k \ln p_k - \ln q_{\alpha_i}^*(k) \right) - \sum_k (p_k - q_{\alpha_i}^*(k)) \ln q_{\alpha_i}^*(k)
\]

This implies that to a first order approximation when \( q_{\alpha_i}^* \) is close to \( p \),

\[
\mathcal{A}(a_i) \simeq -\frac{1}{\mu} \ln \left( 1 + \sum_s p_{\alpha_i}(s) \left( \sum_k p_k \ln p_k - \ln q_{\alpha_i}^*(k) \right) \right)
\]

\[
= -\frac{1}{\mu} \sum_s p_{\alpha_i}(s) \left( \sum_k p_k \ln p_k - \ln q_{\alpha_i}^*(k) \right)
\]

\[
= \frac{1}{\mu} \sum_s p_{\alpha_i}(s) \left( \sum_k p_k \ln p_k - \ln q_{\alpha_i}^*(k) \right)
\]

and

\[
I_e(\alpha_i) = \sum_s p_{\alpha_i}(s) \left( \sum_k p_k \ln p_k - \ln q_{\alpha_i}^*(k) \right) - \sum_k (p_k - q_{\alpha_i}^*(k)) \ln q_{\alpha_i}^*(k)
\]

\[
= \sum_s p_{\alpha_i}(s) \left( \sum_k p_k \ln p_k - \ln q_{\alpha_i}^*(k) \right) - \sum_k \left( \frac{q_{\alpha_i}(k)}{p(k)} - 1 \right) p(k) \ln q_{\alpha_i}^*(k)
\]

\[
\simeq \sum_s p_{\alpha_i}(s) \left( \sum_k p_k \ln p_k - \ln q_{\alpha_i}^*(k) \right) - \sum_k (\ln p_k - \ln q_{\alpha_i}(k)) \left( \ln p_k - \ln q_{\alpha_i}(k) \right)
\]

\[
= \sum_s p_{\alpha_i}(s) \left( \sum_k \left( 1 + \ln q_{\alpha_i}(k) \right) p_k \ln p_k - \ln q_{\alpha_i}(k) \right)
\]

\[24\]
As a result, it follows that:

$$\mathcal{A}(a_i) \simeq \frac{1}{\mu} \sum_s p_{\alpha_i}(s) \left( \sum_k p_k \left( \ln p_k - \ln q_{\alpha_i}^s(k) \right) \right)$$  \hspace{1cm} (2)$$

and

$$I_e(\alpha_i) \simeq \sum_s p_{\alpha_i}(s) \left( - \sum_k \left( 1 + \ln q_{\alpha_i}^s(k) \right) p_k \left( \ln p_k - \ln q_{\alpha_i}^s(k) \right) \right).$$  \hspace{1cm} (3)$$

A comparison of expressions (2) and (3) makes clear that when priors and posteriors are similar, the two indices point in the same direction - as long as it is also true that the $q_{\alpha_i}^s(k)$ vectors are all parallel to the unit vector and that $\ln q_{\alpha_i}^s(k) < -1$, that is, when priors are close to uniform and there are more than two states. Otherwise, cases such as the one provided in Example (2), when posteriors are very informative, are likely to make the indices diverge.

### 7.7 The Case of the Continuum

We have worked with finitely many states to avoid measure-theoretic technicalities. The results in this paper are easy to extend to distributions with a continuum of states. This is useful because many applications assume such a continuum.

**Example 3** Suppose that each signal drawn generates a distribution with conditional normal density $s \sim N(\eta_s, \Sigma_s)$. Let the prior $p$ be normally distributed with $p \sim N(\eta_p, \Sigma_p)$. Then the relative entropy $(d(p\|q_{\alpha_i}^s))$, also called Kullback-Leibler divergence, can be written as follows:

$$d(p\|q_{\alpha_i}^s) = \frac{1}{2} \left( \text{tr} \left( \Sigma_s^{-1} \Sigma_p \right) + (\eta_s - \eta_p)^\top \Sigma_s^{-1} (\eta_s - \eta_p) - \ln \left( \frac{\mid \Sigma_p \mid}{\mid \Sigma_s \mid} \right) - n \right).$$

This implies that $\mathcal{A}(a)$ can be written as follows:

$$\mathcal{A}(a) = -\frac{1}{\mu} \ln \left( \sum_s p_{\alpha}(s) \exp \left( -\frac{1}{2} \left( \text{tr} \left( \Sigma_s^{-1} \Sigma_p \right) + (\eta_s - \eta_p)^\top \Sigma_s^{-1} (\eta_s - \eta_p) - \ln \left( \frac{\mid \Sigma_p \mid}{\mid \Sigma_s \mid} \right) - n \right) \right) \right)$$

25
and also that the expression for $I_e$ is the following:

$$I_e(\alpha) = \frac{1}{2} \ln ((2\pi e)^n |\Sigma_p|) - \sum_s p_{\alpha}(s) \frac{1}{2} \ln ((2\pi e)^n |\Sigma_s|).$$

Thus, the two indices lend themselves to easy computations, and comparisons as that in Example 2 can be readily drawn.

8 Related literature

As mentioned in the introduction, the natural limitation of Blackwell (1953)’s ordering is that it does not provide a complete ordering of information structures. More recent research has since focused on restricting preferences to a particular class. Lehmann (1988) restricts attention to problems with monotone decision rules, and Persico (2000), Athey and Levin (2001), and Jewitt (2007) do so to some more general classes of monotone problems. The main difference between this line of research and our approach is that we provide a complete order through a duality axiom for problems with a restricted set of investment opportunities.\(^{10}\)

Our approach to ranking information transactions is based on a ranking for preferences for information. There are relatively few papers in the literature dealing with the comparison of different agents’ preferences for information. One such study is Grant, Kajii, and Polak (1998) who explore intrinsic preferences for information, that is, preferences that are unrelated to the ability of information to make more profitable decisions. This is very different to our framework, since our agents like information precisely to help them make better decisions. But, interestingly, just as we found in Theorem 2 that risk aversion is related to preferences for information, Grant, Kajii, and Polak (1998) find that their notion of Information Loving is related to the convexity of preferences. Dubra and Echenique (2001) establish the impossibility of representing by a utility function monotone preferences for information about an uncountable set of states of nature. Li (2010) studies\(^{10}\) Ganuza and Penalva (2010) provides a partial ordering of information structures based on various measures of dispersion of distributions, rather than on decision-theoretic considerations. Many of those measures are presented in Shaked and Shanthikumar (2007). They then study the implications of greater informativeness (in their sense) for auction problems.
the relationship between intrinsic preferences of information and the aversion to ambiguity in dynamic decision settings.

Relative entropy plays an important role in our index. Kullback and Leibler (1951) showed that relative entropy measures the mean information per sample for distinguishing between two hypotheses when one of them is true.\footnote{\textsuperscript{11}A maximum likelihood estimator of a parametric model is also a minimizer of the Kullback-Leibler divergence.} Subsequently, Shore and Johnson (1980) provided an axiomatization of relative entropy with respect to the prior as a criterion for model selection.

The relative-entropy measure of proximity of probability distributions appears prominently in many economic settings. For example, Blume and Easley (1992) and Sandroni (2000) show that, in dynamic exchange economies, markets favor agents who make the most accurate predictions when accuracy is measured according to relative entropy. Hansen and Sargent (2010, 2001) introduce into the economics literature a multiple priors model that builds on earlier work in the optimal-control literature. In that model, agents take into account the possibility that their beliefs $q$ may not be correct, and they consider other possible alternatives $p$; the relative likelihood of these alternative distributions is then measured by relative entropy. This model, also called the multiplier preferences model, is in turn a special case of the model of ambiguity aversion in Maccheroni, Marinacci, and Rustichini (2006). Relative entropy has also been used in the reputation model of Gossner (2011) to assess differences between conditional and unconditional predictions about long-run player types. The use of relative entropy in this context allows one to derive explicit bounds on the payoff of the long-run player, thanks to the chain-rule property of relative entropy. However, none of these previous papers in economics uses relative entropy to measure the informativeness of signals or the appeal of information transactions.

Relative entropy is a generalized form of the entropy measure of information that is used to measure costs of information acquisition in rational inattention models. Rational inattention originated in Macroeconomics following the work of Sims (2003) and is now rapidly growing into Microeconomics (see, e.g. Matějka and McKay, 2012; Caplin and Dean, 2013). De Oliveira (2013) provides axiomatic foundations for the entropy costs of information acquisition, and De Oliveira, Denti, Mihm, and Ozbek (2013) for a class of rationally inattentive models that are monotone with respect to the Blackwell ordering.
Outside economics, relative entropy is widely used to measure both informativeness and differences between distributions. In information theory, the Kraft–McMillan theorem\(^\text{12}\) shows that when sending messages to identify a state \(s\) in a set \(S\) which has a certain probability distribution, the Kullback-Leibler divergence quantifies the expected extra message-length needed if a code is optimal for a given (wrong) distribution rather than for one based on the true distribution. Weyl (2007) has used this theorem to propose relative entropy as a good way to learn which is the best scientific theory among those that describe the same data. Soofi and Retzer (2002) provide a summary of the applications of entropy-related indices in statistics and econometrics, and the interrelationships between them. There are numerous applications of relative entropy in a range of disparate fields. Gourieroux, Monfort, and Renault (1987) have proposed the Kullback information criterion as a basis for causality tests in time series analysis. They are used in linguistics, for example, to measure the information content of words (Kuperman, Bertram, and Baayen, 2010; Mishra and Bangalore, 2011); in optics, for measuring the discriminatory power of sensory networks (Ong, Xiaoy, Tham, and Ang, 2009); in hydrology, for assessing data informativeness for risk management (Singh, 1997); in genetics, to measure genetic diversity (Sherwin, 2010); in zoology, where long-run fitness is maximized by the phenotype that adapts itself (best-responds) to the signal which minimizes relative entropy with respect to the true state of the environment (Donaldson-Matasci, Bergstrom, and Lachmann, 2010); and even in archeology, to infer whether a set of findings is consistent with the known facts of a particular prehistoric period (Justeson, 1973). Although many of these applications use relative entropy to measure informativeness, none of them provides a decision-theoretic microfoundation for such use.

## 9 Conclusion

We propose a novel approach that provides a complete ordering of information transactions. The approach also orders information structures, when the transaction price is kept constant. The complete ordering proposed here is dual to the agent’s preferences for information, as stated in Definition 1. We find that only two axioms, duality from preferences for information and

\(^\text{12}\)From Kraft (1949) and McMillan (1956).
homogeneity, yield a cardinal characterization of an index of appeal of information transactions, up to a multiplicative normalization constant. The index has a simple analytic characterization, which is an expectation of the exponential of relative entropy from the prior to the posteriors after signals. This is remarkable since relative entropy has been extensively used as a measure of information gain in computer science and other disciplines. Moreover, the specific appeal formula is actually identical (ignoring the price separable term) to the notion of free energy in theoretical physics (Landau and Lifshitz, 1980). The role of duality in this framework, as well as for measuring riskiness (Aumann and Serrano, 2008), suggests that the approach may be useful in general to index other multidimensional magnitudes of economic interest.

References

A Proofs

This appendix presents the proofs of the results in an appropriate logical order.
A.1 Proof of Theorem 2

We begin by stating and proving several auxiliary lemmas.

Lemma 1 Fix $p$ and consider a sequence $q^n$ of beliefs such that $q^n \to p$. Let $b^n$ be the optimal investment for an agent with beliefs $q^n$. Then, it must be true that $b^n \to 0$.

Proof. If the property does not hold, there exists a sequence $q^n \to p$ and a corresponding sequence of optimal investments $b^n$ together with $\varepsilon > 0$ such that, for every $n$, $\|b^n\|_\infty \geq \varepsilon$. Since $u$ is strictly concave, there exists $a > 0$ such that for every $z$ with $|z| \geq \varepsilon$,

$$u(w + z) \leq u(w) + zu'(w) - a|z|.$$  

We then have for every $n$:

$$V(u, w, q^n) = \sum_k q^n_k u(w + b^n_k)$$

$$\leq \sum_{|b^n_k| < \varepsilon} q^n_k (u(w) + u'(w)b^n_k) + \sum_{|b^n_k| \geq \varepsilon} q^n_k (u(w) + u'(w)b^n_k - a|b^n_k|)$$

$$= u(w) + \sum_{|b^n_k| < \varepsilon} (q^n_k - p^n_k)u'(w)b^n_k + \sum_{|b^n_k| \geq \varepsilon} (q^n_k - p^n_k)u'(w)b^n_k - aq^n_k|b^n_k|,$$

where the last equality uses $\sum_k q^n_k = 1$ and $\sum_k p^n_k b^n_k = 0$. This implies both

$$\lim_{n \to \infty} \sum_{|b^n_k| < \varepsilon} (q^n_k - p^n_k)u'(w)b^n_k = 0$$

and

$$\limsup_{n \to \infty} \sum_{|b^n_k| \geq \varepsilon} (q^n_k - p^n_k)u'(w)b^n_k - aq^n_k|b^n_k| < 0,$$

since for every $n$, there exists $k$ such that $|b^n_k| \geq \varepsilon$. This shows that

$$\limsup_{n \to \infty} V(u, w, q^n) < u(w),$$

which is in contradiction with $V(u, w, q) \geq u(w)$ for every $q$. We conclude that the property holds as claimed. ■
Lemma 2 Fix $p$ and consider $q$ close to $p$. Then, the optimal investment $b(q) = (b_k(q))_{k \in K}$ for an agent with belief $q = (q_k)_{k \in K}$ is

$$b_k(q) = \frac{1}{p_k \rho(w)} (q_k - p_k) + o(\|q - p\|).$$

Proof. The agent’s problem is to maximize $\sum_k q_k u(w + b_k)$ under the constraint $\sum_k p_k b_k = 0$. The solution is uniquely given by the system of first-order conditions:

$$q_k u'(w + b_k) = \lambda p_k,$$

where $\lambda$ is independent of $k$. Using a first order Taylor expansion of $u'(w+b_k)$, we obtain:

$$u'(w) + b_k u''(w) = \lambda \frac{p_k}{q_k} + o(b_k). \tag{4}$$

We multiply each equation by $p_k$ and sum over $k$ to get:

$$u'(w) = \lambda \sum_j \frac{p_j^2}{q_j} + o(b_k). \tag{5}$$

We replace the value of $\lambda$ obtained using (5) into equation (4) and get:

$$b_k = \frac{u'(w)}{u''(w)} \left( \frac{p_k}{q_k} \sum_j \frac{p_j^2}{q_j} - 1 \right) + o(b_k).$$

In vector form, this can be expressed as:

$$b = F(q) + \gamma(b),$$

where $(F(q))_k = \frac{u'(w)}{u''(w)} \left( \frac{p_k}{q_k} \sum_j \frac{p_j^2}{q_j} - 1 \right)$ and $\gamma(b) \in \mathbb{R}^K$ is such that $\|\gamma(b)\| \rightarrow 0$ as $\|b\| \rightarrow 0$.

We now show that $\|b\| = O(\|q - p\|)$. Assume to the contrary that there exists a sequence $q^n \rightarrow p$ and a corresponding sequence $b^n$ such that $\|b^n\| \rightarrow \infty$. We would then have:

$$\frac{\|b^n\|}{\|q^n - p^n\|} \leq \frac{\|F(q^n)\|}{\|q^n - p^n\|} + \frac{\gamma(b^n)}{\|q^n - p^n\|} \frac{\|b^n\|}{\|q^n - p^n\|}.$$
However, a simple computation shows that \(\|F(q^n)\| = O(\|q^n - p^n\|)\), and we know from Lemma 1 that \(\|b^n\| \to 0\); hence, \(\gamma(b^n) \to 0\). This yields a contradiction, and hence the conclusion that \(\|b\| = O(\|q - p\|)\).

We thus have \(\gamma(b) \|q - p\| \to 0\) as \(\|q - p\| \to 0\). We can therefore write

\[
b_k = \frac{u'(w)}{u''(w)} \left( \frac{p_k}{q_k \sum_j \frac{p_j^2}{q_j}} - 1 \right) + o(\|q - p\|)
\]

\[
= \frac{1}{\rho(w)} \left( \frac{q_k \sum_j \frac{p_j^2}{q_j} - p_k}{q_k \sum_j \frac{p_j^2}{q_j}} \right) + o(\|q - p\|)
\]

\[
= \frac{1}{p_k \rho(w)} (q_k - p_k) + o(\|q - p\|),
\]

where the last line uses the fact that \(\lim_{q \to p} \sum_j \frac{p_j^2}{q_j} = 1\).

Lemma 3 Fix \(p\) and consider \(q\) close to \(p\). Then,

\[
V(u, w, q) = u(w) + \frac{1}{2} \sum_k (q_k - p_k)^2 \frac{u'(w)}{\rho(w) p_k} + o(\|q - p\|^2).
\]

Proof. We have

\[
V(u, w, q) = \sum_k q_k u(w + b_k),
\]

where \(b = (b_k)_{k \in K}\) is defined as in Lemma 2. A second order Taylor expansion gives

\[
V(u, w, q) = u(w) + \sum_k q_k b_k u'(w) + \frac{1}{2} \sum_k q_k b_k^2 u''(w) + o(\|b\|^2)
\]

\[
= u(w) + \sum_k (q_k - p_k) b_k u'(w) + \frac{1}{2} \sum_k q_k b_k^2 u''(w) + o(\|b\|^2).
\]

From Lemma 2 we know that \(\|b\| = O(\|q - p\|)\). Hence, we can replace \(o(\|b\|^2)\) by \(o(\|p - q\|^2)\) in the expression above. By substituting \(b_k\) for the
expression in Lemma 2 we obtain:

\[
V(u, w, q) = u(w) + \sum_k \frac{(q_k - p_k)^2}{\rho(w)p_k} u'(w) \\
+ \frac{1}{2} \sum_k \frac{q_k}{\rho(w)^2 p_k^2} (q_k - p_k)^2 u''(w) + o(||q - p||^2)
\]

which is as claimed.

Fix \( p \), and two states \( k, l \in K \). For \( \min\{p_k, p_l\} > \varepsilon > 0 \), let \( q^{\varepsilon,k} \) be given by \( q^{\varepsilon,k}_k = p_k + \varepsilon \) for \( k' \neq k, l \); \( q^{\varepsilon,k}_k = p_k - \varepsilon \). Similarly, \( q^{\varepsilon,l} \) is given by \( q^{\varepsilon,l}_k = p_k + \varepsilon \) for \( k' \neq k, l \); \( q^{\varepsilon,l}_l = p_l + \varepsilon \); and \( q^{\varepsilon,l}_k = p_k - \varepsilon \). Thus, the belief \( q^{\varepsilon,k} \) gives slightly higher weight to state \( k \) and slightly lower weight to state \( l \) than \( p \), whereas \( q^{\varepsilon,l} \) does the opposite. Now consider an information structure \( \alpha(\varepsilon) \) such that with probability \( \frac{1}{2} \), the agent’s posterior is \( q^{\varepsilon,k} \); and with probability \( \frac{1}{2} \) it is \( q^{\varepsilon,l} \). (Such an information structure exists since \( \frac{1}{2} q^{\varepsilon,k} + \frac{1}{2} q^{\varepsilon,l} = p \).)

**Lemma 4** For \( \varepsilon \) close to 0, the maximal price \( \mu(\varepsilon) \) that an agent is willing to pay for \( \alpha(\varepsilon) \) is:

\[
\mu(\varepsilon) = \frac{p_k + p_l}{2\rho(w)p_k p_l} \varepsilon^2 + o(\varepsilon^2).
\]

**Proof.** The maximal price \( \mu(\varepsilon) \) is such that the informational gains exactly compensate the monetary loss. Such a price satisfies the equation:

\[
\frac{1}{2} (V(u, w - \mu(\varepsilon), q^{\varepsilon,k}) + V(u, w - \mu(\varepsilon), q^{\varepsilon,l})) = u(w).
\]

Relying on Lemma 3, we get:

\[
u(w) - u(w - \mu(\varepsilon))) = \frac{u'(w - \mu(\varepsilon))}{2\rho(w - \mu(\varepsilon))} \left( \frac{\varepsilon^2}{p_k} + \frac{\varepsilon^2}{p_l} \right) + o(\varepsilon^2).
\]

This shows that \( \mu(\varepsilon) \to 0 \) as \( \varepsilon \to 0 \), and therefore, by taking a first-order Taylor approximation of \( u(w - \mu(\varepsilon)) \), we obtain:

\[
\mu(\varepsilon) u'(w) + o(\mu(\varepsilon)) = \frac{u'(w) p_k + p_l}{2\rho(w) p_k p_l} \varepsilon^2 + o(\varepsilon^2).
\]
We conclude that:
\[
\mu(\varepsilon) = \frac{p_k + p_l}{2\rho(w)p_k p_l} \varepsilon^2 + o(\varepsilon^2),
\]

as we wanted to show. ■

Having proved this series of lemmata, we now proceed to prove Theorem 2.

**Proof of Theorem 2.** Assume that \( u_1 \) likes information better than \( u_2 \), and consider wealth levels \( w_1 \) for \( u_1 \) and \( w_2 \) for \( u_2 \). The maximal price that \( u_1 \) is willing to pay at wealth level \( w_1 \) for the information structure \( \alpha(\varepsilon) \) is always higher than or equal to the maximal price that \( u_2 \) is willing to pay at wealth level \( w_2 \) for the same information. From Lemma 4 we obtain that for every \( w_1 \), \( w_2 \) and for a small enough \( \varepsilon > 0 \),
\[
\frac{p_k + p_l}{2\rho_u(w_1)p_k p_l} \varepsilon^2 \geq \frac{p_k + p_l}{2\rho_u(w_2)p_k p_l} \varepsilon^2.
\]

Hence, \( \rho_u(w_1) \leq \rho_u(w_2) \), which implies \( \overline{R}(u_1) \leq \overline{R}(u_2) \).

Now assume that \( \overline{R}(u_1) \leq \overline{R}(u_1) \). For every \( z, w_1 \), and \( w_2 \), we have
\[
\frac{u_2'(w_2+z)}{u_2'(w_2+z)} \leq \frac{u_1'(w_1+z)}{u_1'(w_1+z)}.
\]

By integration on \( z \), we have:
\[
\begin{align*}
\ln u_2'(w_2+z) - \ln u_2'(w_2) &\leq \ln u_1'(w_1+z) - \ln u_1'(w_1) & \text{if } z \geq 0; \\
\ln u_2'(w_2+z) - \ln u_2'(w_2) &\geq \ln u_1'(w_1+z) - \ln u_1'(w_1) & \text{if } z \leq 0;
\end{align*}
\]

which is the same as:
\[
\begin{align*}
\frac{u_2'(w_2+z)}{u_2'(w_2)} &\leq \frac{u_1'(w_1+z)}{u_1'(w_1)} & \text{if } z \geq 0; \\
\frac{u_2'(w_2+z)}{u_2'(w_2)} &\geq \frac{u_1'(w_1+z)}{u_1'(w_1)} & \text{if } z \leq 0.
\end{align*}
\]

By a second integration on \( z \), for every \( z \):
\[
\frac{u_2(w_2+z) - u_2(w_2)}{u_2'(w_2)} \leq \frac{u_1(w_1+z) - u_1(w_1)}{u_1'(w_1)}.
\]

Thus, for every \( q \in \Delta(K) \) and \( \mu \geq 0 \):
\[
\frac{V(u_2, w_2 - \mu, q) - u_2(w_2)}{u_2'(w_2)} \leq \frac{V(u_1, w_1 - \mu, q) - u_1(w_1)}{u_1'(w_1)}.
\]

37
And finally, for every information structure $\alpha$,

$$\sum_s p_\alpha(s) V(u_2, w_2 - \mu, q^*_k) - u_2(w_2) \leq \sum_s p_\alpha(s) V(u_1, w_1 - \mu, q^*_k) - u_1(w_1).$$

This implies that for every $w_1, w_2$, if $u_1$ rejects $a = (\mu, \alpha)$ at wealth $w_1$, then $u_2$ also rejects it at wealth $w_2$. ■

A.2 Proof of Theorem 3

The first step in the proof of Theorem 3 is to characterize the optimal investment portfolio for a CARA agent as well as the function $V(u_C, w, q)$. This is done in the lemmata below.

For a CARA agent with coefficient $r$ of risk aversion and wealth level $w$, we consider the problem of optimal portfolio choice when the agent’s belief is $q$. The next lemma shows that the solution is interior when $q$ has full support.

**Lemma 5** Let $q \in \Delta(K)$ have full support. The optimal portfolio for the CARA agent with risk-aversion coefficient $r$ and belief $q$ is independent of $w$, and is given by

$$b_k = -\frac{1}{r}(-d(p || q) + \ln \frac{p_k}{q_k}).$$

**Proof.** The agent’s objective is to maximize

$$\sum_k q_k \exp(-r(w + b_k)),$$

subject to the constraint $\sum_k p_k b_k = 0$. The first-order condition shows that

$$q_k \exp(-rb_k) = \lambda p_k,$$

where $\lambda$ is independent of $k$. We then have, for every $k$,

$$-rb_k = \ln \lambda + \ln \frac{p_k}{q_k}.$$

Summing over these expressions, after we multiply each of them by $p_k$, gives

$$0 = \ln(\lambda) + d(p || q),$$

38
and hence, the result. □

We proceed with a characterization of the function $V(u_C^r, w, q)$. We recall the convention that $\exp(-d(p||q) - rw) = 0$ by continuity if $d(p||q) = \infty$, and state:

**Lemma 6** For every $r, w, q$:

$$V(u_C^r, w, q) = -\exp(-d(p||q) - rw).$$

**Proof.** First, assume that $q$ has full support; hence, $d(p||q)$ is finite. Using the optimal-portfolio characterization of Lemma 5, we obtain:

$$V(u_C^r, w, q) = \sum_k q_k \exp(-r(w + b_k))$$

$$= \exp(-rw) \sum_k q_k \exp(-d(p||q) + \ln \frac{p_k}{q_k})$$

$$= \exp(-rw - d(p||q)) \sum_k q_k \frac{p_k}{q_k}$$

$$= \exp(-rw - d(p||q)).$$

Now assume that $q_{k_0} = 0$ for some $k_0$; hence, $d(p||q) = +\infty$. The investment $b^0$ given by:

$$\begin{cases} b^0_{k_0} = \frac{1-p_{k_0}}{p_{k_0}}, \\
 b_k = 1 & \text{if } k \neq k_0
\end{cases}$$

is such that $\lambda b^0 \in B^*$ for every $\lambda \geq 0$. For every such $\lambda$, we have

$$V(u_C^r, w, q) \geq \sum_k q_k u_C^r(w + \lambda b_k^0)$$

$$= \frac{u_C^r(w + \lambda b_k^0)}{u_C^r(w + \lambda)}.$$ 

Since $\lim_{\lambda \to \infty} \exp(-r(w + \lambda)) = 0$, we have $V(u_C^r, w, q) \geq 0$. On the other hand, $V(u_C^r, w, q) \leq \sup_z u_C^r(z) = 0$. The desired conclusion is therefore that $V(u_C^r, w, q) = 0$. □

We now proceed to the proof of Theorem 3.

**Proof of Theorem 3.** The agent accepts $a$ if and only if

$$\sum_s p_\alpha(s) V(u_C^r, w - \mu, q_\alpha^s) \geq u_C^r(w).$$
If \( a \) is excluding, then the left-hand side of the inequality equals 1, and the inequality is satisfied for all \( r \) and \( w \). If \( a \) is nonexcluding, then the agent accepts \( a \) if and only if
\[
\exp(-rw) \geq \exp(-r(w - \mu)) \sum_s p_\alpha(s) \exp(-d(p\|q^*_\alpha)).
\]
This is equivalent to
\[
\exp(-r\mu) \geq \sum_s p_\alpha(s) \exp(-d(p\|q^*_\alpha)),
\]
which in turn is equivalent to \( r \leq \mathcal{A}(a) \). Thus, for \( r \leq \mathcal{A}(a) \), the agent accepts \( a \) at every wealth level, whereas for \( r > \mathcal{A}(a) \), the agent rejects \( a \) at every wealth level.

\section*{A.3 Proof of the Main Result}

Equipped with Theorems 2 and 3, we can now prove our main result, Theorem 1.

**Proof of Theorem 1.** First assume that \( a_1 \) is more appealing than \( a_2 \), and that \( \mathcal{A}(a_2) \) is finite. By Theorem 3, a CARA agent with a coefficient of risk aversion \( \mathcal{A}(a_2) \) accepts \( a_2 \) at every wealth level. This agent likes information better than itself according to Definition 1 since, by Theorem 3, acceptance or rejection for CARA agents is independent of wealth. Since \( a_1 \) is more appealing than \( a_2 \), this CARA agent also accepts \( a_1 \) at every wealth level, which implies (also by Theorem 3) that \( \mathcal{A}(a_1) \geq \mathcal{A}(a_2) \).

The case in which \( \mathcal{A}(a_2) = \infty \) is dealt with similarly: by Theorem 3 every CARA agent accepts \( a_2 \) at every wealth level, which implies that the same agent also accepts \( a_1 \) at every wealth level. By Theorem 3 again, this implies that we also have \( \mathcal{A}(a_1) = \infty \).

Now assume that \( \mathcal{A}(a_1) \geq \mathcal{A}(a_2) \). Consider two agents \( u_1 \) and \( u_2 \) such that \( u_1 \) likes information better than \( u_2 \). Given wealth levels \( w_1 \) and \( w_2 \), and assuming that \( u_2 \) accepts \( a_2 \) at \( w_2 \), we need to prove that \( u_1 \) accepts \( a_1 \) at \( w_1 \).

By Theorem 2 we have \( \overline{R}(u_1) \leq \overline{R}(u_2) \). Since \( \overline{R}(u_1) > 0 \) and \( \overline{R}(u_2) < \infty \), \( \overline{R}(u_2) \) is positive and finite. Let \( r = \overline{R}(u_2) \). Since \( \overline{R}(u^C_r) = r \), the agent \( u^C_r \) likes information better than agent \( u_2 \) does, by Theorem 2; hence the former accepts \( a_2 \) at any wealth level. By Theorem 3 this means that \( r \leq \mathcal{A}(a_2) \), and hence also \( r \leq \mathcal{A}(a_1) \), so that \( u^C_r \) also accepts \( a_1 \) at any wealth level. Since \( \overline{R}(u_1) \leq r = \overline{R}(u^C_r) \) and \( u_1 \) likes information better than \( u^C_r \) (also by Theorem 2), it follows that \( u_1 \) accepts \( a_1 \) at wealth level \( w_1 \).  

40
A.4 Proof of Theorem 6

Proof. The index $A$ satisfies price homogeneity of degree $-1$ by its definition, and Theorem 1 shows that it satisfies duality. It only remains to prove uniqueness up to a positive multiplicative constant.

Let $B$ satisfy both axioms, and fix an information transaction $a_1 = (\mu_1, \alpha_1)$ such that $A(a_1) \neq 0$. Consider any other information transaction $a_2 = (\mu_2, \alpha_2)$. First assume that $A(a_2) \neq 0$. By homogeneity of $A$, we have:

$$A(a_2) = A\left(\frac{A(a_1)}{A(a_2)}\mu_1, \alpha_1\right).$$

By duality of $A$, $a_2$ is more appealing than $\left(\frac{A(a_1)}{A(a_2)}\mu_1, \alpha_1\right)$. By duality of $B$, this implies:

$$B(a_2) \geq B\left(\frac{A(a_1)}{A(a_2)}\mu_1, \alpha_1\right).$$

Again, by duality of both $A$ and $B$, the converse inequality is also true, so that we have:

$$B(a_2) = B\left(\frac{A(a_1)}{A(a_2)}\mu_1, \alpha_1\right).$$

Finally, by price homogeneity of $B$, we obtain:

$$B(a_2) = \frac{B(a_1)}{A(a_1)}A(a_2).$$

Note that $\frac{B(a_1)}{A(a_1)}$ is independent of $a_2$ and is a positive constant because, if $B(a_1) = 0$, we would also have $B(2\mu_1, \alpha_1) = 0$. This would imply that $(2\mu_1, \alpha_1)$ is more appealing than $(\mu_1, \alpha_1)$, hence that $A(2\mu_1, \alpha_1) \geq A(a_1)$. But this is a contradiction with $A(2\mu_1, \alpha_1) = \frac{1}{2}A(a_1) > 0$.

Now assume that $A(a_2) = 0$. This means that for every $s$, $d(p\|q_{\alpha_2}^s) = 0$; hence, $q_{\alpha_2}^s = p$. Therefore, $\alpha_2$ has no informational content, and all agents reject $a_2$ at every price $\mu_2 > 0$. In particular, it is tautologically true that for every $\varepsilon > 0$, the transaction $\left(\frac{\mu_2}{\varepsilon}, \alpha_1\right)$ is more appealing than $a_2$. Thus, $B\left(\frac{\mu_2}{\varepsilon}, \alpha_1\right) \geq B(a_2)$, and by homogeneity we have $B(a_2) \leq \varepsilon B(a_1)$. Since this is true for every $\varepsilon > 0$, we must have $B(a_2) = 0$.

We have therefore shown the existence of a positive constant $\frac{B(a_1)}{A(a_1)}$ such that, for every $a_2$,

$$B(a_2) = \frac{B(a_1)}{A(a_1)}A(a_2),$$

which completes the proof.
A.5 Proof of Section 5

We begin with an auxiliary lemma:

Lemma 7 An agent \( u \in U_{DA} \) rejects \( a \) at all wealth levels if and only if \( R(u) \geq A(a) \).

Proof. Let \( r = A(a) \). Assume \( R(u) \geq A(a) \). Since \( u \) is DARA, \( p_u(w) > A(a) \) for every \( w \). The same computation as in the proof of Theorem 2 shows that for every \( z \),

\[
\frac{u(w + z) - u(w)}{u'(w)} < \frac{u'_r(w + z) - u'_r(w)}{u'_r(w)}.
\]

If \( q \) has full support, the solution to the maximization problem of \( \sum_k q_k u(w + b_k) \) under the constraint \( \sum_k p_k b_k \leq 0 \) is interior. Let \( b(q) \) achieve this maximum. We have:

\[
\frac{V(u, w - \mu, q) - u(w)}{u'(w)} = \frac{\sum_k q_k u(w - \mu + b_k(q)) - u(w)}{u'(w)} < \frac{\sum_k q_k u'_r(w - \mu + b_k(q)) - u'_r(w)}{u'_r(w)} \leq \frac{V(u'_r, w - \mu, q) - u'_r(w)}{u'_r(w)}.
\]

If \( q \) does not have full support, we still have:

\[
\frac{V(u, w - \mu, q) - u(w)}{u'(w)} = \sup_{b \in B^*} \frac{\sum_k q_k u(w - \mu + b_k) - u(w)}{u'(w)} \leq \sup_{b \in B^*} \frac{\sum_k q_k u'_r(w - \mu + b_k(q)) - u'_r(w)}{u'_r(w)} \leq \frac{V(u'_r, w - \mu, q) - u'_r(w)}{u'_r(w)}.
\]

Note that \( A(a) \leq r \) implies that \( A(a) \) is finite, and hence that \( a \) is nonexcluding; therefore, there exists \( s \) such that \( p_\alpha(s) > 0 \) and \( q^* \) has full support. Hence:

\[
\sum_s p_\alpha(s) \frac{V(u, w - \mu, q^*) - u(w)}{u'(w)} < \sum_s p_\alpha(s) \frac{V(u'_r, w - \mu, q^*) - u'_r(w)}{u'_r(w)} = 0.
\]
where the last equality comes from the fact that the agent $u_r^C$ is indifferent between accepting and rejecting the information transaction $a$. We conclude that agent $u$ rejects $a$ at wealth level $w$.

Now, assume that $R(u) < r$ and choose $r_0$ such that $R(u) < r_0 < r$. Since an agent $u_r^C$ accepts $a$ at any wealth level, an agent $u_{r_0}^C$ strictly prefers accepting $a$ at wealth level 0, which can be expressed as:

$$1 - \sum_s p_\alpha(s) \sup_{b^s \in B^s} \sum_k q^s_k \exp(r_0(\mu + b^s_k)) > 0.$$ 

Let $(b^s)_s$ then be a family of elements in $B^s$ such that:

$$1 - \sum_s p_\alpha(s) \sum_k q^s_k \exp(r_0(\mu + b^s_k)) > 0.$$

Let $w$ be such that $\rho(w - \mu + \min_{s,k} q^s_k) < r_0$. We have $\rho(z) < r_0$ for every $z \geq w - \mu + \min_{s,k} q^s_k$. It follows that by the same computation as in the proof of Theorem 2, for every $s, k$:

$$\frac{u(w - \mu + b^s_k) - u(w)}{u'(w)} \geq \frac{u_{r_0}^C(-\mu + b^s_k) - u_{r_0}^C(0)}{u_{r_0}^C(0)}.$$

Therefore:

$$\sum_s p_\alpha(s)V(u, w - \mu, q^s_\star) - u(w) \geq \frac{\sum_s p_\alpha(s) \sum_k q^s_k u(w - \mu + b^s_k) - u(w)}{u'(w)} \geq \frac{\sum_s p_\alpha(s) \sum_k q^s_k u_{r_0}^C(-\mu + b^s_k) - u_{r_0}^C(0)}{u_{r_0}^C(0)} > 0.$$

Hence, $u$ accepts $a$ at wealth $w$. ■

**Proof of Theorem 4.** Point 1 is a direct consequence of Lemma 7. Point 2 follows from similar arguments as in the proof of Theorem 2. ■

**Proof of Theorem 5.** We first prove that $a_1$ is minimally more appealing than $a_2$ if and only if $A(a_1) \geq A(a_2)$. Assume that $a_1$ is minimally more appealing than $a_2$. Consider a CARA agent with risk aversion level $r = A(a_2)$, such an agent accepts $a_2$ at all (hence some) wealth levels. The same agent must also accept $a_1$ at some wealth level, which by Lemma 7 implies that $A(a_2) = r \leq A(a_1)$. Now assume $A(a_1) \geq A(a_2)$, and consider $u_1 \in U_{DA}$ who minimally likes information better than $u_2 \in U_{DA}$. If $u_2$ accepts $a_2$ at
some wealth level, Theorem 4 and Lemma 7 imply \( R(u_1) \leq R(u_2) \leq A(a_2) \leq A(a_1) \), hence \( u_1 \) accepts \( a_1 \) at some wealth level.

Now we prove that \( a_1 \) is wealth wise more appealing than \( a_2 \) if and only if \( A(a_1) \geq A(a_2) \). Assume that \( a_1 \) is wealth wise more appealing than \( a_2 \). Again, a CARA agent with risk aversion level \( A(a_2) - \varepsilon \) for any \( \varepsilon > 0 \) accepts \( a_2 \) at some wealth level. The same agent (being in \( U_{DA} \)) also accepts \( a_1 \) at some wealth level, which by Lemma 7 implies that \( A(a_2) \leq A(a_1) \). Finally assume that \( A(a_1) \geq A(a_2) \). Consider \( u_1 \in U_{DA} \) who wealth wise likes information better than \( u_2 \in U_{DA} \), both defined on an open interval \( I \) and assume that \( u_2 \) accepts \( a_2 \) at some wealth level \( w \in I \). A CARA agent with degree of risk aversion \( \inf_I \rho_{u_2}(w) \) is wealth wise less risk averse than \( u_2 \) by Theorem 4, hence accepts \( a_2 \) at all wealth levels, and hence, also at \( w \). Since \( u_1 \) is wealth wise less risk averse than \( u_2 \), \( R(u_1) \leq \inf_I \rho_{u_1}(w) \leq \inf_I \rho_{u_2}(w) \). Hence \( A(a_1) \geq A(a_2) \), which implies that \( u_1 \) accepts \( a_1 \) at some wealth level.

\[ \blacksquare \]

A.6 Proof of Theorem 7

Assume that \( a_1 \) uniformly wealth-dominates \( a_2 \). For every \( \varepsilon > 0 \), Lemma 7 shows that an agent \( u_{A(a_1) + \varepsilon} \) rejects \( a_1 \) at all wealth levels. Hence such an agent also rejects \( a_2 \) at all wealth levels, which implies, again by Lemma 7, that \( A(a_1) + \varepsilon \geq A(a_2) \). Since this is true for every \( \varepsilon > 0 \), it follows that \( A(a_1) \geq A(a_2) \).

For the converse, assume that \( A(a_1) \geq A(a_2) \), and that \( u \in U_{DA} \) rejects \( a_1 \) at all wealth levels. Then by Lemma 7, \( R(u) \geq A(a_1) \geq A(a_2) \), and \( u \) also rejects \( a_2 \) at all wealth levels.

A.7 Proof of Proposition 1

**Proof.** Assuming that \( \alpha_1 \) is more informative than \( \alpha_2 \) in the sense of Blackwell, and fixing any arbitrary wealth level \( w \), then any CARA agent who rejects \( (\mu, \alpha_1) \) at wealth level \( w \) also rejects \( (\mu, \alpha_2) \) at wealth level \( w \). It follows from the characterization of \( A \) in Theorem 3 that \( A(\mu, \alpha_1) \geq A(\mu, \alpha_2) \).

\[ \blacksquare \]
A.8 Proof of Proposition 2

Proof. Fix any wealth level. From Theorem 3, a CARA agent with coefficient of risk aversion $A(\mu, \alpha_2)$ accepts both transactions $(\mu, \alpha_1)$ and $(\mu, \alpha_2)$ at wealth $w$; this agent therefore also accepts the transaction $(\mu, \lambda\alpha_1 \oplus (1-\lambda)\alpha_2)$ at that wealth level. This shows that

$$A(\mu, \lambda\alpha_1 \oplus (1-\lambda)\alpha_2) \geq A(\mu, \alpha_2).$$

Now consider $\varepsilon > 0$. Again from Theorem 3, a CARA agent with coefficient of risk aversion $A(\mu, \alpha_1) + \varepsilon$ rejects both transactions $(\mu, \alpha_1)$ and $(\mu, \alpha_2)$ at wealth $w$; this agent therefore also rejects the transaction $(\mu, \lambda\alpha_1 \oplus (1-\lambda)\alpha_2)$ at that wealth level. This shows that

$$A(\mu, \alpha_1) + \varepsilon \geq A(\mu, \lambda\alpha_1 \oplus (1-\lambda)\alpha_2)$$

for every $\varepsilon > 0$, and hence that

$$A(\mu, \alpha_1) \geq A(\mu, \lambda\alpha_1 \oplus (1-\lambda)\alpha_2).$$

A.9 Proofs of Theorems 8 and 9

Proof. We first prove Theorem 9. Agent $u^c_x$, accepts an information transaction $a = (\mu, \alpha)$ at prior $q$ if and only if:

$$\sum_s p_a(s)V(u, w - \mu, q^s) \geq V(u, w, q).$$

Once we use the expression of Lemma 6, this becomes equivalent to:

$$\exp(-d(p||q)) \geq \exp(r\mu) \sum_a p_a(s) \exp(-d(p||q^s)), $$

which is in turn equivalent to

$$r \leq A(a, q).$$

Theorem 8 follows from Theorem 9 just as Theorem 1 follows from Theorem 3.
A.10 Proof of Proposition 3

Proof. We prove the proposition using the following auxiliary decision problem. In the first stage, the agent can either accept information transaction $a$ or reject it. If the agent accepts $a$, then a signal $s$ is drawn from $\alpha$ and the agent can either accept the information transaction $b_s$ or reject it. If the agent rejects $a$, no other information transaction is offered to the agent. Once the agent has acquired some information (or none), any asset in $B^*$ may be purchased; then the state $k$ is realized, and the agent receives the corresponding payoff.

Assume that for every $s$, $A(b_s, q_s) \geq A(a)$, and consider an agent $u_C^{A(a)}$ at any wealth level and any prior $p$. In the sequential decision problem, assuming that $a$ is accepted in the first stage by this agent, then $b_s$ is accepted in the second stage for every $s$. Also, $a$ is accepted in the first stage even if the option of acquiring $b_s$ in the second stage is absent. Therefore, $a$ is also accepted with the option of acquiring $b_s$ in the second stage. Hence, an optimal strategy for the agent is to accept $a$, and then accept $b_s$ no matter what $s$ is. In particular, this strategy is better for the agent than not acquiring any information transaction. This shows that the agent accepts $a + b$, and hence that $A(a + b) \geq A(a)$.

Now assume that for every $s$, $A(b_s, q_s) \leq A(a)$, and consider an agent $u_C^{\rho}$ with $\rho > A(a)$ at any wealth level and any prior $p$. In the sequential decision problem, assuming that $a$ is accepted in the first stage, it is optimal for this agent to reject $b_s$ after every signal $s$. Hence, the decision to acquire $a$ in the sequential decision problem is equivalent to the decision to acquire $a$ alone, and so this agent rejects $a$. Hence, the optimal strategy for the agent is to reject information. In particular, not acquiring any information is better than acquiring $a$, which is itself better than acquiring $a$ and $b_s$ following every $s$, so that no information is better than $a + b$. Therefore, the agent rejects $a + b$, which shows that $A(a + b) < \rho$ for every $\rho > A(a)$. This implies that $A(a + b) \leq A(a)$.

The third point follows immediately from the first and second points. ■
